

# Conducting simple Emission Scenarios

Philip Peck  
28.02.2007

# Outline

---

- Definitions
- Review of the bottom-up emission factor approach
  - Modeling future activity rates
  - Modeling future emission factors
  - Modeling technology penetration rates
- Models and tools for emission scenarios

# Feedback obtained after the July 2006 workshop

- About which topics would you like to learn more to support your professional work?

## How to conduct an Emission Scenario

# Feedback obtained after the July 2006 workshop

- About which topics would you like to learn more to support your professional work?

Tools and modeling approaches for emission scenarios

# What are emission scenarios?

- *A plausible **quantitative** description of how emissions in the future **may** develop, based on a coherent and internally consistent set of **assumptions** (“scenario logic”) about **key relationships** and **driving forces**.*

*(IPCC)*

# Models and tools

- Emission scenarios typically use **quantitative models** built from a number of **mathematical equations**.
- A **model** is a **representation of a system**. A good model behaves sufficiently like the real system that conclusions can be drawn from the model's behaviour to aid in making decisions about the real system.
- A **tool** is a PC software that computes the equations of the model.

# Integrated Assessment Modeling (IAM)

- “An **interdisciplinary** process of **structuring knowledge** elements from various scientific disciplines in such a manner that all relevant aspects of a **complex societal problem** are considered in their mutual coherence for the benefit of **decision-making**” (Rotmans, 1998).
- Emission scenarios are typically one component of Integrated Assessment Models for air quality management.

# General approaches for emission scenarios

## ■ socio-economic

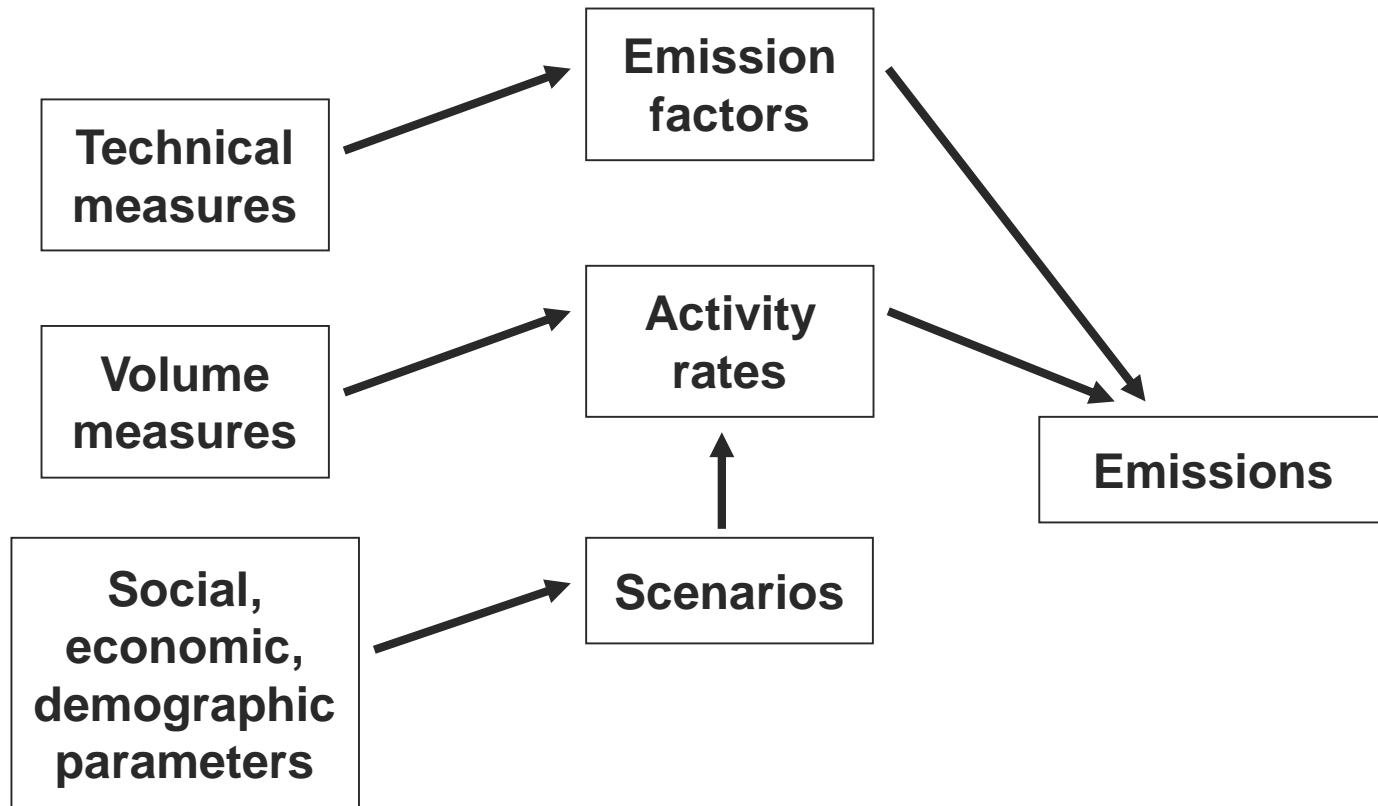

- correlate emissions with socio-economic time series, such as GDP development, without accounting in detail for technological change
- top-down approach

## ■ technology based

- considers explicitly technological change
- emission factor approach is widely used, mainly due to the fact that technological change became a prevailing parameter
- bottom-up approach, can be rather detailed and resource-intensive

# Technology-based, bottom-up approach

# Technology-based, bottom-up approach

# The fundamental formula

$$E = A \times \sum_{k=1}^n (F_k \times P_k)$$

E: emissions

A: activity rate

F: process level  
emission factors

P: activity share or  
penetration rate  
of a technology  
within a sector

k: technology type

Source: EEA

**Activity rate**, e.g.

- electricity consumption (kWh)
- transport volume (Pkm / tkm)
- steel production (tons)

**Process level emission factor**, e.g.

- $g_{SO_2} / kWh_{el}$
- $g_{NO_x} / tkm$
- $g_{SO_2} / ton_{steel}$

**Activity shares or penetration rates** of a technology (k) within a sector

- eventually determined by the behaviour of people
- legislative requirements
- technology acceptance
- etc.

$$E = A \times \sum_{k=1}^n (F_k \times P_k)$$

**Sectoral emission factor**

# The fundamental formula

## Data sources for emission inventories (PAST)

# The fundamental formula

## Data sources for emission inventories (PAST)

- E: emissions
- A: activity rate
- F: process level emission factors
- P: activity share or penetration rate of a technology within a sector
- k: technology type

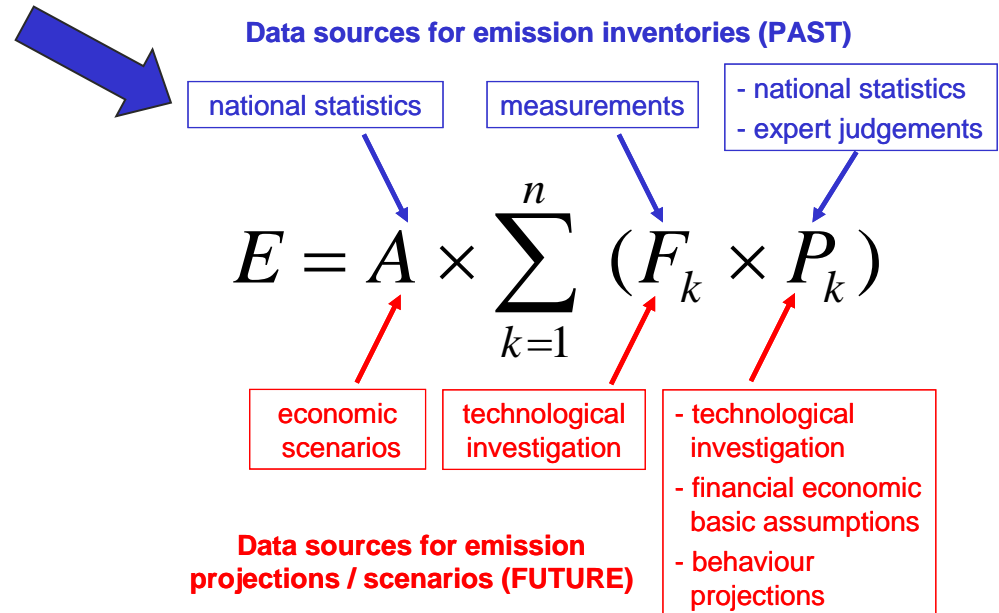

## Data sources for emission projections / scenarios (FUTURE)

# Key assumptions & data quality

- Some aspects of the future are relatively **easy to predict**
  - e.g. a 20 year old consumer of 2025 is already born
  - economic growth can be derived from the experience of other comparable economies in the past
  - long planning and investment horizons in the energy sector make this sector transform at slow rates
- In other fields, **uncertainty is much higher**
  - political stability and overall policy directions
  - energy and world oil prices
  - technological innovation

# The link between inventories and projections / scenarios

- Each emission projection must be based on an **existing emission inventory** as a starting point.

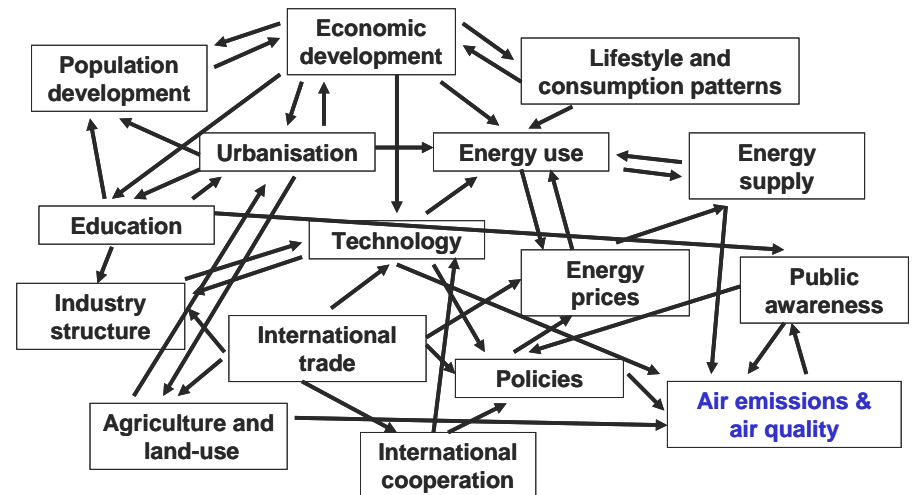

# The link between inventories and projections / scenarios

- Each emission projection must be based on an **existing emission inventory** as a starting point.
- The main difference between an **emission inventory** and an **emission projection / scenario** is the time reference.

# There are many driving forces behind future emissions...

- Population
- Economic and social development
- Energy
- Technology
- Agriculture and land-use
- Policies

**Data collection and modeling of causal interrelations is a big task!**

# Modeling future activity rates

- Future activity rates are determined by numerous socioeconomic factors, e.g.
  - Population
  - land use
  - GDP overall or industry volume
  - number of households and vehicles

# Examples of economic factors that determine future activity rates

- The **world oil price** influences the fuel consumption behaviour of industry as well as of private consumers and the competitiveness of alternative fuels
- The **electricity price** in a country influences consumption and the competitiveness of electricity towards other fuels in the end-use stage.
- The **dynamic structure of the power generating sector** determines future activity rates and fuel consumption. The development depends on e.g.:
  - availability of domestic energy carriers
  - the legislative framework of the power sector (state-controlled vs. deregulated)
  - trade connections and national energy policies with regard to security of supply
  - political and public attitude towards nuclear power
  - national environmental policies and international agreements

# Examples of economic factors that determine future activity rates

- The **dynamic structure of the transport sector** is driven by economic growth and rising incomes. Peoples' income is the most decisive factor that influences private car ownership.
  - Typically vehicle ownership grows relatively slowly at the lowest levels of per-capita income, then about twice as fast as income at middle-income levels (from \$3,000 to \$10,000 per capita), and reaches saturation at the highest levels of income.
  - Projecting these trends into the future would, for instance, mean that in India with a projected increase of per-capita GDP by 3.5 % annually in the 2002-2030 period, vehicle ownership would increase by 7 % annually until 2030 (Dargay, Gately, & Sommer, 2006).
- Similarly, economic growth and **national and international trade** are key factors that influence the activity rate in the freight sector.
- **Urbanization** and the growth of cities entails increasing needs for commuter transport service.

# Modeling future emission factors

- Emission factors on technology level undergo external influences e.g. by environmental legislation requiring compliance with certain emission limit values.
- Consequences are retrofitting of existing technologies and improved performance of new technologies and phasing out of old technologies
- Modeling (average sectoral) future emission factors requires information about
  1. Phase-in of new technologies (e.g. vehicles with state-of-the-art flue gas cleaning)
  2. Phase-out of old polluting technologies (e.g. old vehicles without any flue gas cleaning)

# Modeling the phase-out of “old” vehicles

Beta Model for Car Scrapping

Source: Peck (2003)

# Environmental polices and technology penetration

- Technology penetration is influenced, amongst others by
  - availability and costs of new technologies
  - investment programs
  - energy prices
  - environmental legislation.
- The enforced penetration of technologies by environmental legislation may even cause the disappearance of certain technologies even in a short time perspective.
  - Example: mandated conversion of all public transport buses, taxis, and three-wheelers to compressed natural gas in Delhi, India in 2000–2002.

# Emission scenario variants

- Simple baseline growth scenario
  - Considers only changes in the activity rate, emission factors in future years remain constant to the base year.
- Baseline scenario
  - Considers future activity rates and future emission factors taking into account the impacts of the presently decided legislation on emission controls.
- Alternative policy scenario
  - Considers future activity rates and future emission factors taking into account the impacts additional policies

# Models and tools that may support emission scenarios

- the **RAINS** integrated assessment model for air pollution and greenhouse gases
- the **TREMOVE** transport model
- the **TIMER** energy demand and supply and emission model
- the Long-range Energy Alternatives Planning tool (**LEAP**)
- the **MARKAL** energy-economic-environmental model
- **GAINS** - a model about Greenhouse Gas and Air Pollution Interactions and Synergies
- and many more....
- see RAPIDC scenario handbook for an overview

# Scenario and IAM exercise

- More in the Scenario and Integrated Assessment Modeling exercise later
- For the exercise we will use the SIM-AIR tool to...
  - project future activity rates,
  - built some simple alternative policy scenarios,
  - find a cost-effective combination of prevention and control measures to attain emission reduction targets.

**Summary Sheet**    CBL = Current Baseline; TBL = Target Year Baseline; TC = Target Year Controlled

	2007	2017	TC	Change
<b>Total Emissions (tons/year)</b>				
PM10	106,841	145,479	134,522	-9%
SO2	136,242	169,193	164,587	-3%
NOx	111,327	160,724	128,842	-25%
CO2	22,079,241	25,448,242	25,014,263	-29%

% Contribution (PM10 Emissions)	2007	2017	TC	Change
